

**Abstract Text:****Abstract**

*Background:* The breasts are important for the woman's psychological well-being, which may be negatively affected by distortions of breast size and shape. Improvements in self-esteem and sexuality are important psychological factors associated with motivation for cosmetic surgery. Mammoplasty is among the most sought-after and performed cosmetic procedures. The aim of this study was to evaluate the impact of aesthetic breast surgery on woman's sexuality.

*Methods:* This study was conducted in a plastic surgery clinic of a hospital university in Brazil, between 2009 and 2012. Forty-six patients with hypomastia and 30 patients with breast hypertrophy, who expressed the desire for aesthetic breast surgery, were selected for the study. The patients were assessed preoperatively and 6 months postoperatively using the Sexual Quotient - Female version scale (SQF). The SQF is a validated Brazilian questionnaire to assess sexual function. It contains of 10 items covering five domains of female sexual function: desire and interest, foreplay, excitement and harmony, comfort, and orgasm and satisfaction. Higher SQF scores indicate better sexual functioning.

*Results:* There was a significant increase in the mean total SQF score after surgery in both groups ( $p < 0.001$ ). No significant improvement in desire and comfort was reported by patients who underwent breast augmentation and in comfort by patients who underwent breast reduction. Improvement in sexuality after surgery was observed in both groups, which is consistent with the literature.

*Conclusion:* Aesthetic breast surgery has a positive impact on the sexuality of patients.
